

Q.1.

## ASSIGNMENT-2

Algorithm  $\text{SelectKthRanked}(A[1 \dots n], B[1 \dots m], k)$

```

{
    if A.length = 0
        return B[k]

    if B.length = 0
        return A[k]

    mid1 =  $\lceil n/2 \rceil$ 
    mid2 =  $\lceil m/2 \rceil$ 

    if (mid1 + mid2 <= k)
        if (A[mid1] > B[mid2])
            return  $\text{SelectKthRanked}(A[1 \dots n], B[mid2+1 \dots m], k - mid2)$ 
        else
            return  $\text{SelectKthRanked}(A[mid1+1 \dots n], B[1 \dots m], k - mid1)$ 
    else
        if (A[mid1] > B[mid2])
            return  $\text{SelectKthRanked}(A[1 \dots mid1-1], B[1 \dots m], k)$ 
        else
            return  $\text{SelectKthRanked}(A[1 \dots n], B[1 \dots mid2-1], k)$ 
}

```

Explanation: (Note: 'k' refers to the number of elements we need at any point to reach the kth element.)

1) We first define the base cases:

i) if A empty, return B[k]

ii) if B empty, return A[k]

2). At each call, we compute  $mid1$  and  $mid2$ .  
If  $mid1 + mid2 \leq K$ :

Here, there is a possibility that the elements  $A[1..mid1]$  and  $B[1..mid2]$  might all be in the first  $K$  elements ~~of  $A \cup B$~~ .

Here, there are 2 cases:

Case-1:  $A[mid1] > B[mid2]$

In this case there might be elements to the right of  $mid2$  which are lesser than  $A[mid1]$ . Also, there might be elements to the left of  $mid1$  which might be greater than  $B[mid2]$ .

But the portion of elements -  $B[1..mid2]$

must definitely  <sup>$mid1$</sup>  be present in the first  $K$  elements ~~of  $A \cup B$~~ .

So we recurse only on:

$B[mid2+1..m]$  and  $A[1..n]$ .

Also,  $K = K - mid2$  (since  $B[1..mid2]$  are surely in the first  $K$  elements)

Case-2:  $B[mid2] > A[mid1]$

Similar to The above explanation except than in this case, we recurse on:

$A[mid1+1..m]$

$K = K - mid1$  (since  $A[1..mid1]$  elements have been <sup>known to</sup> surely be in the first  $K$  elements)

If  $\text{mid1} + \text{mid2} > K$ :

Here, all the elements  $A[1 \dots \text{mid1}]$  and  $B[1 \dots \text{mid2}]$  cannot be in the first  $K$  elements we need.

Case-3:  $A[\text{mid1}] > B[\text{mid2}]$

Since only  $K$  elements are required,  $A[\text{mid1} \dots n]$  cannot be in the first  $K$  elements we need.

So we recurse only on:

$A[1 \dots \text{mid1}-1]$  and  $B[1 \dots m]$

$K$  remains the same since we still need  $K$  elements.

Case-4:  $A[\text{mid1}] < B[\text{mid2}]$

Similarly to the above case, except that here we only recurse on:

$A[1 \dots n]$  and  $B[1 \dots \text{mid2}-1]$

$K$  remains the same since we still need  $K$  elements.

Running time:

- 1> The base cases take  $O(1)$  time.
- 2> Computing  $\text{mid1}$  and  $\text{mid2}$  takes  $O(1)$  time.
- 3> In the worst case we recurse until both  $A$  and  $B$  contain only one element each.
- 4> Our array sizes of  $A$  and  $B$  are reduced

by half in every alternate call (in the worst case)  
until both have one element each).

$$\therefore T(n) = O(\log(n) + \log(m))$$

## 2. Cascading Waterfall.

input: Set of  $n$  points in a plane ( $P$ )

output: Set of non-dominated points in  $P$  i.e.  $S$

Divide-and-conquer Approach:

Algorithm Cascade( $P[1..n]$ )

if  $n=1$  return  $P$

if  $n=2$  return  $\max_{x,y}(P[1], P[2])$

$m = \text{find-Median}(P[1..n])$

Let  $L, R$  be 2 sets

for  $i=1$  to  $n$

if  $P[i].x < m$

put  $P[i]$  in set  $L$

else

put  $P[i]$  in set  $R$

set  $S_1 = \text{Cascade}(L)$

set  $S_2 = \text{Cascade}(R)$

$y_{\min} = \infty$   
for  $k=1$  to  $S_2.\text{size}()$

if  $S_2[k].y < y_{\min}$

$y_{\min} = S_2[k].y$

for  $k=1$  to  $S_1.\text{size}()$

if  $S_1[k].y < y_{\min}$

remove  $S_1[k]$  from  $S_1$

return  $S_1 \cup S_2$

Explanation:

1) The base cases are trivial.

2) We find the median of the points in the current set w.r.t.  $x$ -coordinates

of the points which takes  $O(n)$  time.  
3) We put the points <sup>with x-coordinate</sup> less than  $X_{\text{median}}$  (or  $m$ ) in set  $L$  and the remaining in set  $R$ . This is done by traversing through the array in  $O(n)$  time.

4) We recursively call the function on  $L$  and  $R$ , getting sets  $S_1$  and  $S_2$  respectively of the non-dominated points in  $L$  and  $R$ .

5) We observe that <sup>all</sup> the non-dominated points of  $S_2$  must be in our resulting list.

6) However, any point in  $S_1$  with  $y$ -coordinate less than the minimum  $y$ -coordinate in  $S_2$  cannot be in the resulting list. We eliminate all such points.

7) Find  $y_{\min}$  takes  $O(n)$  time and eliminating points in  $S_2$  also takes  $O(n)$  time.

8) We return  $S_1 \cup S_2$ .

### Running Time:

1) The base case takes  $O(1)$  time.

2) Median find takes  $O(n)$  time.

3) Putting points into  $L$  and  $R$  takes  $O(n)$  time.

3> Finding  $y_{\min}$  takes  $O(n)$  time.

4> Eliminating points in  $s_1$  takes  $O(n)$  time.

All operations other than recursive calls take  $O(n)$  time.

$$\begin{aligned}T(n) &= T(n/2) + O(n) + O(n) + O(n) + O(n) \\&= T(n/2) + O(n) \\&= O(n \log n)\end{aligned}$$

Note: Each operation other than <sup>a</sup> recursive call takes  $O(n)$  time for all recursive calls at a level. i.e.  $O(n)$  time is needed for an operation to be executed in all recursive calls at any level.

Q.3. We need to find the maximum length of a convex subsequence  $x_1 \dots x_m$  s.t. for all  $1 < i < m$

$$x_{i-1} + x_{i+1} > 2x_i \quad (1).$$

Recursive Algorithm:

Algorithm Convex ( $A[1 \dots n]$ )

```
{
    if  $n \leq 2$                                 // Base case
        return  $n$ 
    result = Convex Rec(1, 2)
    if (result != 2)
        return result
    else
        return 0
}
```

Convex Rec ( $i, j$ )

```
{
    best = 2
    for  $k = j+1$  to  $n$ 
        if ( $A[i] + A[k] > 2 \cdot A[j]$ )
            best = max { best, 1 + Convex Rec( $j, k$ ) }
    return best
}
```

Explanation:

- 1) if  $n \leq 2$  return  $n$ .  
Since (1) is vacuously true.
- 2) when Convex Rec(1, 2) is called:  
1) either there is a longer convex subsequence beginning at  $A[1]$ , or  
2) not  
We use a for loop to iterate over values of  $k$  where  $j+1 \leq k \leq n$ .
- 3) If the value 2 is returned there is no convex subsequence.

Note: Here  $i$  and  $j$  are the first 2 indices of the array <sup>portion</sup> we are recursing on.  
i.e.  $A[i, j, \dots n]$

Dynamic Programming solution :

We can use a table of size  $n \times n$  to store the values. The parameter  $i$  is represented by the rows and ' $j$ ' by the columns.

best = 2  
if (condition satisfied)

best =  $\max \{ \text{best}, \text{ConvexRec}(j, k) \}$   
return best

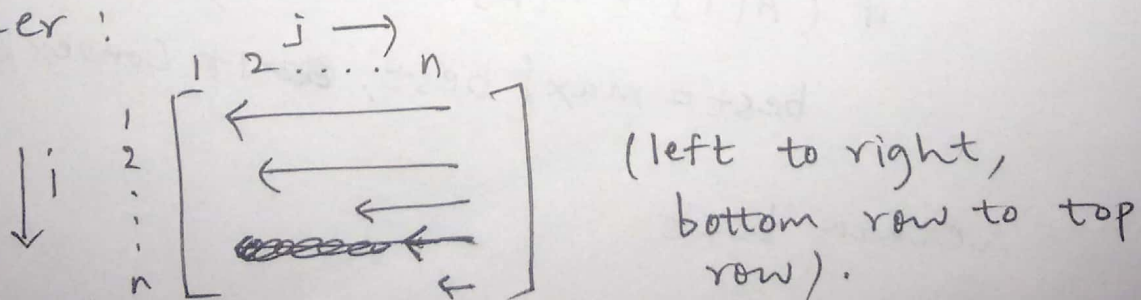

Here,

$$i < j < k$$

$$j < k \leq n$$

To compute  $B[i][j]$ , we need all values of  $B[j][k]$ , where  $j \leq k \leq n$

The table must be filled in the following order :

The last row is empty since  $B[n][j]$  cannot exist  $\forall j$ .

Q.3 > The logic here is that whenever  $B[j][k]$  is called then the condition:

$$A[i] + A[k] > 2A[j]_{\text{valid}} \quad \text{--- (1)}$$

must be true, i.e. there are indices  $i, j, k$  such that the above condition is true.

So the length of the subsequence  $\text{convex}(i, j)$  or  $B[i][j]$  should be at least 3 ~~if we start~~ or more.

That is why the base cases (last column entries are set to 2).

$B[i][j]$  is also set to 2 inside the second 'for' loop before iterating over  $k$ .

4 > We need the value of  $B[1][2]$  to be returned by the first recursive call.  
if  $B[1][2] = 2$ , it means there is no  $j, k \leq n$  for which condition (1) is true.  
Hence, we return 0 in that case.

Running time:

- 1) There are approximately  $O(n^2)$  table entries.
  - 2) Each table entry takes  $O(n)$  time to compute since we must iterate over values of  $k$ .
  - 3) Other operations and base cases are  $O(1)$  time
- $$T(n) = O(n^2 \cdot n) = O(n^3)$$

Algorithm ConvexDP( $A[1..n]$ )  
 { if ( $n \leq 2$ ) return  $n$   
 Initialise  $B[1..n][1..n]$

for  $i = 1$  to  $n-1$

$B[i][n] = 2$

for  $i = n-2$  down to  $1$

for  $j = n-1$  down to  $i+1$

$B[i][j] = 2$

for  $k = j+1$  to  $n$

if ( $A[i] + A[k] > 2A[j]$ )

$B[i][j] = \max\{B[i][j], 1 + \overset{B[j][k]}{\text{ConvexDP}(A[j..k])}\}$

if ( $B[1][2] \neq 2$ )

return  $B[1][2]$

else

return  $0$

}

Explanation:

1) Last column entries are set to '2' (base cases, helps in length calculation).

2). Three 'for' loops

i) one for ' $i$ ' =  $n-2$  to  $1$

ii) one for ' $j$ ' =  $n-1$  to  $i$

iii) We set  $B[i][j] = 2$  and iterate over  $k$  values of  $k$

Q.4. MAXIMUM SUBARRAY PRODUCT :

Algorithm Max-Sub-Product ( $A[1 \dots n]$ )

```
{
  if  $n = 0$ 
    return 0
  if  $n = 1$ 
    return  $A[1]$ 

  ans =  $A[1]$ 
  cur-max =  $A[1]$ 
  cur-min =  $A[1]$ 

  for  $i = 2$  to  $n$ 
    prev = cur-max
    cur-max =  $\max \{ \text{max cur-max} * A[i], A[i], \text{cur-min} * A[i] \}$ 
    cur-min =  $\min \{ \text{min prev} * A[i], A[i], \text{cur-min} * A[i] \}$ 

    ans =  $\max \{ \text{ans}, \text{cur-max} \}$ 

  return ans
}
```

Explanation :

1) The base cases handle the trivial scenarios.

2> The variables  $cur\_max$ ,  $cur\_min$  and  $ans$  are set equal to  $A[1]$  initially.

3> for  $i = 2$  to  $n$ .  
 $cur\_max$  is <sup>set to</sup> the maximum of 3 things  
 $A[i]$ ,  $cur\_max * A[i]$ ,  $cur\_min * A[i]$ .

- i)  $cur\_max$  stores the maximum product in the currently running subarray.
- ii)  $cur\_min$  <sup>stores minimum product</sup> is useful if  $A[i]$  is negative to multiply with (since  $(-) \times (-) = +$ )
- iii) if  $A[i] = 0$ , both  $cur\_min$  and  $cur\_max$  are set to 0, which means that the max subarray cannot end at 0. So, the max subarray product has already been calculated or we start again.  

---

 $cur\_min$  is set to the minimum of 3 things:  
 $cur\_max * A[i]$ ,  $cur\_min * A[i]$ ,  $A[i]$

4> At each iteration, the variable  $ans$  is updated.

$$ans = \max(ans, cur\_max)$$

5> We return ' $ans$ ' when the control exits the for loop.

Running Time:

1> Base cases are  $O(1)$  time.

Q.2 → Alternate approach (Non divide-and-conquer)

Algorithm Cascade ( $P[1 \dots n]$ )

Merge-sort-Y( $P$ )

$x_{\max} = -\infty$

for  $k = n$  down to 1

if  $P[k].x \geq x_{\max}$

add  $P[k]$  to set  $S$ .

$x_{\max} = P[k].x$

return  $S$ .

Explanation:

1) We first sort the points based on their  $y$ -coordinates (in increasing order).

2) Starting from the last point in the sorted array (point with highest  $y$ -coordinate value), we add a point to our set  $S$  if  $P[i].x \geq x_{\max}$ .  
i.e. we are <sup>now</sup> finding points in a non-decreasing order of  $x$  coordinates.

Running Time:

1) Merge-sort-Y( $P$ ) takes  $O(n \log n)$  time

2) The for loop takes  $O(n)$  time. Operations inside the for loop take  $O(1)$  time.

$$T(n) = O(n) + O(n \log n)$$

$$T(n) = O(n \log n)$$
